41 Carbon; climatic gradients; decomposition *k* rate; leaf litter; nitrogen; precipitation; temperature;
42 turnover.

Abstract

Carbon (C) and nitrogen (N) cycling under future climate change is associated with large uncertainties in litter decomposition and the turnover of soil C and N. In addition, future conditions (especially altered precipitation regimes and warming) are expected to result in changes in vegetation composition, and accordingly in litter species and chemical composition, but it is unclear how such changes could potentially alter litter decomposition. Litter transplantation experiments were carried out across 6 European sites (4 forest and 2 grasslands) spanning a large geographical and climatic gradient (5.6 – 11.4 °C in annual temperature 511 – 878 mm in precipitation) to gain insight into the climatic controls on litter decomposition as well as the effect of litter origin and species.

The decomposition *k* rates were in overall higher in warmer and wetter sites than in colder and drier sites, and positively correlated with the litter total specific leaf area. Also, litter N content increased as less litter mass remained and decay went further.

Surprisingly, this study demonstrates that climatic controls on litter decomposition are quantitatively more important than species or site of origin. Cumulative climatic variables, precipitation, soil water content and air temperature (ignoring days with air temperatures below zero degrees Celsius), were appropriate to predict the litter remaining mass during decomposition (M_r). M_r and cumulative air temperature were found to be the best predictors for litter carbon and nitrogen remaining during the decomposition. Using mean annual air temperature, precipitation, soil water content and litter total specific leaf area as parameters we were able to predict the annual decomposition rate (k) highly significantly.

1. Introduction

In non-fertilized ecosystems, such as most grasslands and forests, the nitrogen (N) flux in litter is the dominant N input into the soil (Berg and McClaugherty, 2008). The total gross amount of N mineralized in the soil is a product of the total litter mass production rate, the litter decomposition rate and the litter N content. Site climatic characteristics strongly affect the litter decomposition rate by modifying conditions for decomposers to act and transform organic litter matter into forms readily usable for plants (Berg et al., 1993). When both nutrients and decomposable carbon sources are present, temperature and soil moisture within certain ranges catalyze litter decomposition by enhancing soil biota's activity (Berg and McClaugherty, 2014a). Therefore, sites with different precipitation regimes and air and soil temperatures can present different litter decomposition rates. Soil characteristics, soil moisture (Bradford et al., 2016) and its microbial abundance and composition (Allison et al., 2013), and the species-related characteristics of litter also play an important role in the decomposition. Leaf litter may vary greatly in the elemental composition (Berg and McClaugherty, 2008), content of toxic chemicals such as terpenoids and alkaloids that are synthesized to protect against herbivory but also inhibiting soil microbes (Ormeño et al., 2009), anatomical traits like leaf mass per area, and mechanical characteristics like leaf tensile strength (Cornelissen and Thompson, 1997), resistance to fracture (Wright and Illius, 1995), and leaf toughness (Gallardo and Merino, 1993).

Many efforts have been made to model the carbon (C) and N release from decomposing litter across different climates (Bonan et al., 2013;Liski et al., 2005;Zhang et al., 2010). Models are needed to predict future levels of soil N availability and turnover rate. The decomposition k rate is likely positively correlated with mean annual precipitation and temperature (Zhang et al., 2008). Moreover, in Europe, climate change is in overall expected to increase air temperature, and reduce precipitation in southern countries, while both temperature and precipitation are predicted to increase in northern countries (Jacob et al., 2014). Therefore, models accounting for the changes in litter decomposition are urgently needed in order to understand the C and N dynamics in changing climate.

In order to gain insight into future climate effects on litter decomposition the biological and climatic controls of the decomposition need to be solved. Measuring litter decomposition across climatic transects is a technique which allows one to quantify the response of litter decomposition traits in relation to the specific climatic variations along a transect (Johansson et al., 1995). On the

other hand, to measure the effects of litter species or chemical composition on decomposition, one can compare the decomposition rates from litter with different characteristics in a specific climate (Gallardo and Merino, 1993). For this reason, accounting with litter from different climates is certainly beneficial for these types of experimental setups. This is because leaf litter of the same species originated in different climates may have different chemical composition, specific leaf area, etc., thus adding more range of variability to the analysis. As an example, leaves with a small specific area can be expected to be physically tough in terms of resistance to penetration and therefore mass loss and decomposition rate (Cornelissen, 1996). In this article, we present a combination of both experimental approaches to study the effects of both, the climatic and the litter substrate characteristics, on the decomposition process. We carried out litter transplantation experiments to study litter decomposition rates across forest and grassland ecosystems from warm temperate to boreal Europe, with the major aim to separate the biological and climatic controls on litter decomposition. The specific aims of the study were: (1) to assess the actual leaf litter decomposition rates and the C and N amounts remaining in the litter, (2) to study these as a function of the climatic characteristics and litter species, and (3) to generate a simple data-based model to predict the litter mass and litter C and N contents remaining after increasing time-steps of decomposition.

In order to assess the rapid changes in first days of the decomposition, which has been proposed important with respect to mass loss of the litter (Berg and McClaugherty, 2014b), we performed an intensive litter bag sampling during the first month of decomposition at Hyytiälä. The existence of a first leaching phase within the first days of decomposition may in typical litterbag experiments pass unnoticed, although it could according to Berg and McClaugherty (2014b) account for ca. 10% of accumulated mass loss.

The European continent includes a large range of ecosystems differing in mean annual temperatures and cumulative annual precipitation. We were especially interested in comparing temperate sites with northern sites, which would present seasons with mean air temperature below zero Celsius degrees, because we hypothesize that litter decomposition is slowed down by freezing temperatures and lack of liquid water. Therefore, one of our goals is to make the model valid for temperate and northern climates.

2. Material and methods

2.1. Study sites

The study was conducted at six sites of the NitroEurope Integrated project (2006-2011 – http://www.nitroeurope.eu/). The sites covered various climates and ecosystems representative of the European continent and were each dominated by a single tree or grass species. The forest sites are Hyytiälä in Finland (Korhonen et al., 2013;Portillo-Estrada et al., 2013), Männikjärve in Estonia (Carter et al., 2012;Portsmuth et al., 2005), Sorø in Denmark (Pilegaard et al., 2011), and Speulderbos in the Netherlands (Portillo-Estrada et al., 2013), while the grassland sites are Easter Bush in the UK (Jones et al., 2011) and Bugac in Hungary (Machon et al., 2015). The details of the sites are provided in Table 1.

2.2. Experimental design and litter collection

We used the litterbag method (Bocock and Gilbert, 1957) and carried out reciprocal litter transplantation experiments to study the decomposition process from two perspectives: as an effect of species-related litter characteristics and as an effect of environmental conditions in the site of decomposition. Foliage litter produced by the dominant species of each site was shipped to all other similar ecosystem sites for decomposition under a different environmental condition to the original. In short, the litter samples were let to decompose at each site and samples were collected at regular intervals over the period of one year, after which the litter mass loss and C and N contents were analyzed.

At the forest sites dominated by evergreen conifers (Hyytiälä, Männikjärve and Speulderbos), the senescent litter material was collected in litter traps placed above the forest floor and harvested once every month throughout the year 2008. At the deciduous forest site Sorø, the litter collection was done analogously, but only during the litterfall period between September - November 2008. At the grassland sites, current-year grass litter was harvested in late autumn by clipping the dead leaves at the base. In all cases, the litter was air-dried at room temperature and mixed every two days to avoid the onset of decomposition of non-aerated wet litter. Once the constant mass was reached, the litter was stored in air-tight bags until the start of the experiment.

All the litter collected was shipped to the same lab (Estonian University of Life Sciences) where the litter corresponding to leaves and needles was separated from the other litter fractions (e.g. cones, bark, twigs, etc.). All the leaf litter belonging to the same site was mixed together to create a standard mix of litter per site. This was done to avoid a bias in the decomposition rates due to temporal differences in litter C and N contents occurring throughout the year for conifers as showed by Portillo-Estrada et al. (2013) in Hyytiälä and Speulderbos conifer forests, and during the litter fall period for the deciduous species (Niinemets and Tamm, 2005). Moreover, mixing the litter collected from different litter traps of a site minimized the potential spatial differences in leaf anatomy (e.g. specific leaf area) occurring within a site.

Flat-shaped litter bags, made out of nylon screen (1 mm mesh size, 15 × 15 cm), were filled with 5.5 ± 0.01 g of air dry (48 h oven-drying at 60 °C) leaf material. The mesh size was considered small enough to prevent biomass loss through the mesh (for the conifer Douglas fir (*Pseudotsuga menziesii*) litter bags, a double layer of tissue was used to minimize the risk of losing leaf needles through the mesh), yet large enough to permit aerobic activity and entry of small soil animals (though excluding earthworms). A color label was inserted in the litter bags to identify their original content (plant species and site origin) during the decomposition.

2.3. Litter transplantation and decomposition

Leaf litter from the four forest sites was shipped to all four forest sites for decomposition, and leaf litter from the grassland sites was sent to the two grassland sites. Altogether, a total of 288 tree litter bags was used for the decomposition experiments at forest sites.

— Forest sites: Decomposing litter was sampled at five sampling times throughout the year. At each date, three replicate bags with litter from each site of origin (four forest sites) were collected at each site of destination (5x3x4x4 = 240 litter bags). Additionally, in Hyytiälä, three replicate litter bags were collected at four sampling times during the first month of decomposition, (4x3x1x4 = 48 litter bags).

— Grasslands: For the grass litter, 60 litter bags were prepared, corresponding to five sampling times during the year, three replicate litter bags per litter origin and two grassland sites were collected (5x3x2x2 = 60 litter bags).

Immediately before installing the litter bags at the sites, the litter bags were moistened by spraying

them with deionized water. After moistening, the bags were placed on the topsoil for decomposition. Each bag was fastened to a stainless steel or PVC stick with a nylon thread. The stick was pushed into the soil, in order to keep the bags in place. At each site, the litter bags were installed in the autumn at a representative day at or close to peak litterfall for forest sites and peak leaf die-off for grassland sites (see Table 1 for dates). Thus, the decomposition period of all the replicate litter bags within a site begun on the same date.

The mass remaining after the specified periods of decomposition was measured by randomly harvesting three replicate litter bags of each litter type of the same origin, later, the mass of the three replicates was averaged. The litter bags were collected on days 2, 5, 9 and 16 after the start of the decomposition treatment in Hyytiälä. In all sites, the bags were also collected approximately in 1, 2, 3, 6 and 12 months after the start. The litter bags were transported to the lab, where the remaining litter mass was oven-dried at 60 °C for 48 hours and weighed. The dried litter samples were then sent to the laboratory at the Estonian University of Life Sciences where the samples were post-processed and analyzed for C and N content and leaf area.

2.4. Analysis of carbon and nitrogen content and leaf traits

The content of each litter bag was ground to a fine powder and the total C and N content per dry mass were determined by a Vario MAX CNS elemental analyzer (Elementar Analysensysteme GmbH, Hanau, Germany) to the nearest 0.01%. The litter N content at different times since the start of decomposition, and the litter N content at the end of the first year of decomposition (N_f) were normalized with respect to the initial litter content (N_0) to estimate the relative N loss through the decomposition treatment.

Specific leaf area was measured in a subsample of the initial (not subjected to decomposition) dried litter mixture. Leaf samples were weighed (0.5 to 1 g) and carefully spread over an A4 flatbed scanner glass avoiding overlap between the leaves, and the leaves were scanned at 300 dpi. The RGB color image of the leaves was processed to estimate the projected litter specific leaf area [m^2 kg^{-1}] as described by Portillo-Estrada et al. (2015). The total specific leaf area was estimated from the projected specific leaf area by considering different leaf section shapes for different leaf types: the section of *Festuca pseudovina* was approximated to a circle; the section of *Pinus sylvestris* leaves was consider hemicircular; *Fagus sylvatica* and *Lolium perenne* leaves were considered flat, thus the

projected area was multiplied by two; and for *Pseudotsuga menziesii*, the projected specific leaf area was multiplied by a factor of 2.3 obtained from measurements of needle circumference to width ratio from the leaf cross-sections under a light microscope. The total specific leaf area represented the maximum leaf surface exposed to potential microbial attack and other physical agents during decomposition.

2.5. Litter decomposition rate

The annual decomposition rate constant, k [year^{-1}] (Olson, 1963) was calculated by fitting the fraction of litter mass remaining vs. time of sampling relationships according to the equation:

$$\ln(m_t/m_0) = -kt, \quad (1)$$

where m_t is the remaining mass of litter after time t [year], and m_0 is the original mass of litter. Six log-transformed data points (five sampling times plus the initial litter mass) corresponding to the average litter mass of the three replicate bags harvested at each decomposition time step were used in each case.

A pairwise comparison (Holm-Sidak at a significance level of $P < 0.05$) test was used to find differences in k between litter types across the decomposition sites.

Litter turnover rate [year] was estimated as the inverse of k (Feng, 2009).

2.6. Meteorological data

Data on air temperature at 0.5 to 4 m height and soil temperature at 2 cm depth, precipitation, air relative humidity and soil water content at 6 cm depth were retrieved from the NitroEurope database (Owen et al., 2011). The retrieved 30-minute average air and soil temperature data were averaged daily and a mean annual air (T_a) and soil (T_s) temperatures were calculated for each site. As the sites spanned over a wide climatic gradient (Table 1), two additional variables for cumulative temperature were created, one for soil ($T_{c,s>0}$) and other for air temperature ($T_{c,a>0}$). The characteristics were computed by summing up the Celsius degrees of days of which daily average temperature was above 0 °C from the start date of the decomposition until the date of the litter collection. These excluded the time periods when water was frozen, and better characterized the control of temperature on the decomposition process. This suggestion was tested in the following analysis.

2.7. Modelling analysis

In order to statistically predict the percentage of litter mass remaining from the initial litter mass (M_r) and the C and N contents in litter relative to initial values (C_r and N_r) at a certain decomposition time, we generated linear mixed effect models including all meteorological parameters and their two-way interactions that individually presented high explanatory power (Pearson correlation coefficient) with the key dependent variables: cumulative air and soil temperature ($T_{c,s>0}$ and $T_{c,a>0}$), cumulative precipitation, air relative humidity, and soil water content. Land use was included as a two-level categorical factor (forests and grasslands) in all models as well, and M_r was used as an additional independent variable in the models of C and N. Litter origin was used as a random factor in all models.

Minimum value of the Akaike information criterion (AIC-value) was used as the criterion for choosing the best model. AIC is a measure of the relative quality of a statistical model for a given set of data, and models with an AIC value less than different by a value of 5 were considered equivalent. We ended up with relatively simple models for the four studied characteristics (M_r, C_r, N_r and k rate). Model selection was done in R (R Core Team, 2013), with the package nlme: linear and nonlinear mixed effects models (Pinheiro et al., 2013).

256 ## 3. Results

257

258 ### *3.1. Litter mass loss during decomposition*

259 The decomposition during the first 100 days was faster than that in the remaining period in all sites
260 and for all types of litter (Fig. 1). Analysis of the early-stage decomposition at Hyytiälä further
261 indicated that the mass loss rate (6 to 12%) was most pronounced during the first couple of days of
262 decomposition (Fig. 1g). This rapid loss was followed by a slow-down in the decomposition and a
263 small increase in the litter mass in the subsequent days so that in one month 87-92% of initial mass
264 was remaining (Fig. 1g). After three months of decomposition, we identified a general decrease in the
265 mass loss rate in all the forest and grassland sites (Fig. 1a-f). In all the sites and litter species, there
266 was a general drop in litter remaining mass during the first months followed by a constant mass over
267 the period of 100-200 days corresponding to the winter period, and more pronounced where a snow
268 cover was present (Fig. 1c,d).

269 The tree litter remaining mass after one year of decomposition differed between the litters of
270 different origin when decomposing in the same site. Nevertheless, a trend of higher remaining mass in
271 the Northern sites Hyytiälä (mean ± SE value was 71.0±2.7%) and Männikjärve (69.1±1.8%) was
272 observed when compared to the more Southern sites Sorø (61.5±2.4%) and Speulderbos (56.9±4.6%)
273 (Fig. 1a-d). In more detail, the decomposition of conifer litter followed a similar trend in all forest
274 sites, characterized by a greater mass loss than that for the broadleaved beech litter. This difference
275 was more pronounced at the sites with a higher mean annual air temperature (Table 1), with
276 Speulderbos being the site where the remaining mass differed most between conifer and broadleaved
277 litter types. Regarding the conifer litter, Douglas fir (*Pseudotsuga menziesii*) litter decomposed faster
278 in the first months than *Pinus sylvestris* litter in Sorø, Männikjärve and Hyytiälä (Fig. 1b,c,d). The
279 remaining mass of *Pinus sylvestris* over the decomposition period did not differ (P = 0.392; paired
280 Student's t-test) between the litter originated at Hyytiälä and Männikjärve. Also there was no
281 difference (P = 0.669; paired Student's t-test) in the remaining mass at the end of the decomposition.

282 The temporal dynamics of the remaining mass of grass litter was very similar for both types of
283 litter (Fig. 1e,f). After one year of decomposition, the remaining mass of litter was substantially
284 smaller at Easter Bush (mean value 19.8%) than at Bugac (46.6%).

285 The average standard error for the three replicate litter bags of the litter mass remaining after one

286 year was 0.7% across all sites. Within the given site, the litter mass remaining after one year since the
287 start of the decomposition did not show differences among leaf litters with different origin (One way
288 repeated measures ANOVA test, $P > 0.05$; Fig. 1). Thus, the decomposition showed a marked
289 dependency on the decomposition site characteristics, rather than on litter type. As an exception, mass
290 loss of *Fagus sylvatica* litter from Sorø decomposed in Speulderbos was slower than that of conifer
291 litters (Holm-Sidak pairwise multiple comparison test, $P < 0.05$; Fig. 1a).

292 The values of the decomposition rate constant, k, were calculated as the slope of a linear fit (N = 6)
293 using log-transformed data of remaining litter mass (Eq. 1). The Pearson correlation (r) coefficient
294 across all species and sites was very high (average ± SE of 0.940±0.010; $P < 0.05$ in all cases).
295 Decomposition k rate was negatively correlated with the total specific leaf area in tree species (r^2 =
296 0.38; $P = 0.011$), but did not correlate to the initial N content ($r^2 = 0.021$; $P = 0.59$).

297

298 ### *3.2. Relationships between litter decomposition rates and site climatic*
299 ### *characteristics*

300 T_a and P for different decomposition sites were positively correlated (r^2 = 0.57), although
301 marginally significant (P = 0.08; N = 6). Cumulative air temperature ($T_{c,a>0}$) and cumulative
302 precipitation (P_c) measured at each sampling time along the year were positively correlated across the
303 sites ($r^2 = 0.91$; $P < 0.0001$). Cumulative soil water content (W_c) was positively correlated with P_c (r^2
304 = 0.81; $P < 0.0001$) and $T_{c,a>0}$ ($r^2 = 0.70$; $P < 0.0001$).

305 Collectively, the remaining litter mass at different stages of decomposition was negatively
306 correlated with $T_{a>0}$ and P in forest (Fig. 2a,b) and grassland (Fig. 2c,d) sites.

307 The decomposition rate constants, k, of all forest decomposition experiments together correlated
308 positively with the mean annual temperature (T_a) of the decomposition site ($r^2 = 0.45$; $P = 0.0043$; Fig.
309 3a). The correlation was high for each individual litter type: $r^2 = 0.99$ ($P = 0.0065$) for *Pinus sylvestris*
310 (Hyytiälä), $r^2 = 0.80$ ($P = 0.10$) for *Pinus sylvestris* (Männikjärve), $r^2 = 0.91$ ($P = 0.045$) for *Fagus*
311 *sylvatica* (Sorø), and $r^2 = 0.94$ ($P = 0.029$) for *Pseudotsuga menziesii*. The value of k was also
312 positively correlated with the site mean annual precipitation (P) (Fig. 3b). Analogously, the higher T_a
313 and P, the more litter mass was lost after one year of decomposition (Fig. 3c,d). As a consequence of
314 the correlations of mass loss and k with site climatic variables, the estimated litter turnover time was
315 negatively correlated with T_a (Fig. 3e) and P (Fig. 3f).

316 The values of k at each site were lower for the broad-leaved *Fagus sylvatica* (Sorø) litter compared
317 to the conifer *Pinus sylvestris* (Hyytiälä) (P = 0.001) and *Pinus sylvestris* (Männikjärve) (P = 0.002)
318 litter types, and marginally significantly lower from the k values for *Pseudotsuga menziesii* (P =
319 0.060). Similarly, the pairwise tests showed that the litter mass loss after one year of decomposition
320 (Fig. 3c,d) and estimated turnover time (Fig. 3e,f) calculated for each site depended on the litter type,
321 showing statistical differences between the broadleaved *Fagus sylvatica* (Sorø) litter and the other
322 three conifer litter types, with no differences between conifer litters.
323

324 ### *3.3. Litter carbon and nitrogen contents through decomposition*

325 Analogously to litter mass, C and N contents were expressed relative to the initial level at the
326 beginning of the decomposition in order to compare the dynamics along different litter types (Fig. 4).
327 Pooling all the decomposition data together, forest litter C content non-linearly increased during the
328 decomposition process (Fig. 4a), in contrast with grassland litter, that remained constant through the
329 decomposition period (Fig. 4b). Litter N content increased during the first year of decomposition for
330 both forest and grassland litters (Fig. 4c,d), although during the first 10 days of decomposition it
331 remained constant for the four forest litter types at Hyytiälä (Fig. 4c inset). Therefore, the C:N ratio
332 steadily decreased during the first year for both types of litter (Fig. 4e,f).
333 The litter N content after different decomposition periods relative to the initial value was
334 positively correlated with the cumulative litter mass loss across all decomposition experiments (Fig.
335 5). However, there was a slight decrease of litter N content during the first period of decomposition (at
336 around 10% of cumulative mass loss) (Fig. 5).
337 The final to initial N content ratio (N_f:N_0) in the forest litter showed a positive trend if plotted
338 against site's T_a and P (Fig. 3g and h) such that at warmer and more humid decomposition sites, litter
339 N content increased more than at colder and drier sites.
340

341 ### *3.4. Results of the statistical modeling analysis*

342 The best model for M_r contained three independent cumulative meteorological variables, air
343 temperature and precipitation, soil water content and the site type factor (grassland or forest), while
344 the models for both C and N were strongest with only remaining litter mass, air temperature and land-
345 use.

346 The percentage of remaining litter mass relative to the initial value (M_r) at forest sites was
347 calculated as

348 $$M_r = 94.51 - 0.04873 \times P_c + 0.00959 \times T_{c,a>0} - 0.00206 \times W_c, \quad (2)$$

349 and for grassland sites as

350 $$M_r = 84.63 - 0.04873 \times P_c - 0.00059 \times T_{c,a>0} - 0.00206 \times W_c. \quad (3)$$

351 Where P_c is the cumulative precipitation [mm], $T_{c,a>0}$ the cumulative air temperature [ºC] on days
352 where daily average temperature was above 0 ºC, and W_c is cumulative soil water content in
353 percentage.

354 The percentage of carbon content in litter relative to the initial value (C_r) at forest sites was
355 calculated as

356 $$C_r = 117.86 - 0.17172 \times M_r - 0.00041 \times T_{c,a>0}, \quad (4)$$

357 and for grassland sites as

358 $$C_r = 99.23 + 0.01081 \times M_r - 0.00041 \times T_{c,a>0}. \quad (5)$$

359 The percentage of nitrogen content in litter relative to the initial value (N_r) at forest sites and
360 grasslands was calculated as

361 $$N_r = 187.51 - 0.9282 \times M_r - 0.03156 \times T_{c,a>0} - 0.00037 \times M_r \times T_{c,a>0}. \quad (6)$$

362 In addition, the decomposition k rate was calculated by a linear model ($r^2 = 0.96$; $P < 0.0001$) as a
363 function of site's mean annual air temperature accounting days with daily average above 0 °C ($T_{a>0}$),
364 mean annual precipitation (P), mean soil water content in percentage (W), and litter total specific leaf
365 area (S_{LA}) as

366 $$k = 4.711 - 0.8601 \times T_{a>0} - 0.0040 \times P + 0.02162 \times W - 0.02140 \times S_{LA} + 0.000827 \times$$
367 $$T_{a>0} \times P - 0.00373 \times T_{a>0} \times S_{LA}, \quad (7)$$

368 and for grassland sites as,

369 $$k = 5.425 - 0.8601 \times T_{a>0} - 0.0040 \times P + 0.02162 \times W - 0.05761 \times S_{LA} + 0.000827 \times$$
370 $$T_{a>0} \times P - 0.00373 \times T_{a>0} \times S_{LA}. \quad (8)$$

371 The P values as well as individual standard errors of the modeled parameters for each equation can
372 be seen in Table 2. In Figure 6 we plot the modeled data (M_r, C_r, N_r, and k) against the observed.
373

4. Discussion

4.1. Litter mass loss during decomposition

Decomposition experiments usually do not focus on the very first days of decomposition (e.g. Vestgarden (2001)) but measure the remaining litter mass in monthly intervals after the beginning of the decomposition. However, there are experiments showing that the remaining mass data over time follows a curvilinear relationship (Pérez-Suárez et al., 2012), thus assuming that the highest mass loss rate occurs during the first days. Our study confirms with experimental data that the mass loss measured at Hyytiälä after one month of decomposition is mainly due to the high mass loss occurring in the very first days, being the absolute maximum rate of the decomposition during the whole period. This few-days period, known as the leaching phase, is driven by the loss of water extractable compounds that physically leak from the sample (Berg and Laskowski, 2005;Cotrufo et al., 2015). As a conclusion, we assumed that litter mass loss followed a simple exponential decay function from the second day of decomposition, thus a double exponential model to calculate k decomposition rate would not apply to our data.

Further in the first month of decomposition, we observed variations in the remaining litter mass including mass increases relative to the previous sampling during the first month of decomposition (Fig. 1g). This could be related to the invasion of microorganisms: mainly fungal mycelia and microbes (Dighton, 2007). Variations in the remaining litter mass have also been shown in later periods than the first month (Liu et al., 2015;Gallardo and Merino, 1993), and has seldom been studied during the first days. Hence, this is yet another motivation to measure the decomposition process during the first days of the experiment focusing on the dynamics of microbial activity and colonization of the litter substrate.

After three months of decomposition, the litter mass loss rate decreased generating a *plateau* shape at around 100 days of decomposition as observed in Figure 1. This was also found by other authors (Liu et al., 2015;Zhang et al., 2014). The generation of a *plateau* was not noticeable in the litter decomposed in Männikjärve (Fig. 1c) because the third sampling was not done during the snow cover period but after it. We speculate that the dynamic of the litter remaining mass could have been similar to the one observed at Hyytiälä (Fig. 1d), revealing also a noticeable decrease in the decomposition rate during the winter after three months of decomposition. We theorize that the slower decomposition

404 rate phase was generated by the combination of the following factors: Firstly, this period coincided
405 with the winter period, where lower air and soil temperature and the presence of a snow cover or the
406 lack of liquid water in some sites reduced the decomposition rate. To corroborate this hypothesis, we
407 found that the remaining biomass and the input of heat to the system estimated by the cumulative air
408 temperature were correlated (Fig. 2a,c). In addition, the decomposition rate increased after the winter
409 period. Secondly, the decomposition usually begins by the more digestible fractions of the litter
410 substrate such as soluble carbohydrates sucrose or glucose (Mansfield and Bärlocher, 2005),
411 generating a faster decomposition rate during the first months. Consequently, after the initial leaching
412 phase, when the substrate is less decomposable, the leaf litter mass loss rate slows down, and
413 collectively with the winter effect creating a *plateau*.
414 In most of the cases, the remaining litter mass did not depend on the litter type, being statistically
415 similar during the decomposition for each site. The exception was *Fagus sylvatica* litter from Sorø
416 when decomposed in Speulderbos. In this case, after the pairwise comparison, two clearly distinct
417 groups were identified, coinciding with the different nature of the leaf litter: the remaining mass of
418 conifer litter differed with the broad-leaved deciduous leaf litter. The decomposition of grass litter
419 types showed a strong influence by the decomposition sites' climatic characteristics and not between
420 litter types. This was noticeable in the high similarity of the remaining litter mass dynamic of the grass
421 litter when decomposing in the same site, as well as by the similar values achieved of remaining litter
422 mass after one year of decomposition.
423
424 ### *4.2. Litter carbon and nitrogen content during decomposition*
425 Nitrogen is released from leaf litter during decomposition firstly due to leaching and secondly
426 because it is consumed as a substrate by decomposing organisms. Berg and Laskowski (2005) showed
427 that the content of N in the litter sample increases with time of decomposition. They argued that litter
428 is colonized by decomposing organisms and since N is usually a limiting nutrient to soil biota, it may
429 actively be brought into the decomposing leaf through ingrowing fungal mycelia. As a result, the N
430 content in the whole sample (including the litter substrate and the decomposers) increased. Our study
431 corroborates the positive trend of N content over decomposition time (Fig. 4c,d) and cumulative mass
432 loss (Fig. 5). These results make the current year litter layer an important sink of N during the first
433 year of decomposition, being richer in N as climate is warmer and wetter (Fig. 3g and h). This can

434 also have effects in the N turnover in future climate scenarios in the frame of a global change, since T_a
435 and P is predicted to increase during the present century for the Atlantic to boreal European climates,
436 where our forest study sites are found (Jacob et al., 2014).

437 The litter C content during the decomposition followed a different dynamic between tree and grass
438 litter types: the decomposition had almost no effect (r^2 = 0.008) on the C content in grass litter whilst
439 it resulted in a rise in the C content in tree litter. We hypothesize that fungal hyphae and mycorrhizae
440 growing on the litter substrate could have brought considerable amounts of C and N onto the litter
441 samples, and the overall C content in grass litter be biased by that increase, consequently keeping the
442 carbon loss and carbon gain in equilibrium. Subsequently, the difference between tree and grass litter
443 was taken into account as a random effect in the equations (Eq. 4 and 5), and satisfactorily generated
444 highly significance models for both land use types. We found no distinction between the prediction of
445 N_r during decomposition (Eq. 6) for grass and forest litter, supposedly because this is the limiting
446 factor in all the ecosystems and N content dynamics were similar across the litter decomposing in all
447 sites.

448

449 ### *4.3. Leaf litter decomposition traits across different climates and litter types*

450 The relationships studied with empirical data allowed us to generate a few models including most
451 of the recurrent traits when studying litter decomposition: litter mass loss, and C and N contents
452 during the decomposition process. Remarkably, the models for forest litter performed satisfactorily
453 (Fig. 6) for different species and origins, including conifer and deciduous litter, with a high range of
454 initial N and C contents and total specific leaf area. After the highly significant relationships between
455 the litter remaining mass with the climatic characteristics (cumulative air temperature and
456 precipitation), and the relationships between the decomposition rate, mass loss and litter turnover with
457 T_a and P, we inferred that the climatic characteristics could be sufficient predictors for estimating the
458 speed of the decomposition process. Additionally, we found that the models benefited from including
459 the land use (forest/grassland) as a fixed factor. We observed that in the grassland sites, the remaining
460 litter mass was highly influenced by the decomposition site characteristics and not by the litter
461 species. Similarly, in the forest sites, there was a certain trend of lower remaining mass at a certain
462 decomposition time as the site presented a warmer and wetter climate, resulting in a higher turnover
463 rate, as studied by Kirschbaum (2000) in the American continent.

With this experiment we found two key points in the relationships of litter decomposition traits with the climatic variables. Firstly, the correlations of the litter traits (remaining mass, and C and N contents) with climatic variables (air temperature, precipitation, and soil water content) were better when transforming the climatic variables to cumulative instead of using annual climatic averages for the given sites. This allowed us to study the decomposition process as a function of the temperature and availability of moisture at each decomposition step along the year. Secondly, using $T_{c,a>0}$ allowed to overcome the fact that certain periods of the year are not favorable for decomposition; that is when the air temperature is ≤ 0, water is frozen and microbial activity is essentially stopped. As shown previously, we detected that the decomposition slowed down during winter time as well as during snow cover periods, and therefore, discarding the days with mean temperature below 0 °C increased the significance of our models. This variable has certain resemblance to the *degree days* used to describe and predict plant growth, which usually uses the lower temperature limit at around 10 °C. As addressed in the introduction, using $T_{c,a>0}$ and $T_{>0}$ is especially important for Northern sites, which present long periods of freezing temperatures and litter decomposition is virtually stopped. We believe these variables should be taken in account for future modelling analysis and predictions.

Equations 2 and 3 performed a highly significance prediction for the litter mass remaining in the decomposition sites with only knowing P_c, $T_{c,a>0}$, and W_c, which is of paramount importance to extrapolating the litter turnover speed in these regions and in a climate change scenario. The importance of using cumulative variables in this particular case is that these can incorporate seasonal variations in the precipitation and temperature regimes, as is predicted to happen in Europe (Jacob et al., 2014).

We found high correlations between the cumulative precipitation (P_c) and air temperature ($T_{c,a>0}$) along the decomposition period, and individually with C_r and N_r, and consequently the C_r and N_r models rejected one of both variables (Eq. 4-6). This happens because using $T_{c,a>0}$ as a predictor for C_r and N_r was sufficient for explaining much of the variation, and adding P_c would not increase the explaining power of the models. Therefore, when including both climatic variables, the model AIC-value increased, P_c was not significant and thus was discarded. Similarly this happened with air and soil temperature variables ($T_{c,a>0}$ and $T_{c,s>0}$) when the model rejected one of both, choosing $T_{c,a>0}$ as the most significant. In conclusion, because climatic variables were highly correlated with each other in our sites, in some cases the models rejected predictors which explained similarly the variation of the

494 independent variables, and finally only few predictors were needed for the models, which was one of
495 the aims of this paper. Similarly, Liski et al. (2003) used few climatic parameters (air temperature,
496 precipitation and evapotranspiration) to predict the litter first-year mass loss. In the same way, our
497 study was performed in a range of European climates which kept certain relationship between P and
498 T_a, therefore we cannot predict goodness of our models in more extreme climates where this
499 relationship would not be kept (e.g. semi-arid climate in SE Spain or subarctic climate in Lapland).
500 We found a strong effect of the climatic characteristics on the decomposition of different litter
501 types, corroborated by similar trends in different litter types when decomposing in the same site. We
502 found that the broad-leaved litter performed lower k rates than the conifer litter, and this could be a
503 consequence of significantly higher specific leaf area in the broad-leaved litter. Therefore, the
504 prediction models of tree litter k rates improved when including the initial total specific leaf area as a
505 characteristic (Eq. 7 and 8). Contrarily, the initial chemical composition (C and N contents) were
506 excluded from the equations.
507 Overall, despite having several climatic variables as inputs into the models, the AIC results were
508 more favorable when the number of variables were less and the equations got simpler. In conclusion,
509 having reached a simple model is in fact highly relevant when estimating these decomposition traits
510 with few meteorological data available.

5. Conclusions

We found strong climatic influence driven by air temperature, precipitation and soil water content on the litter mass remaining during the first year of decomposition in different types of litter. Models with few climatic parameters were enough to predict the remaining litter mass, decomposition k rate, C_r, and N_r content with high certainty.

Leaf litter mass loss can be very important in the first couple of days of decomposition and it deserves special attention for future studies. Litter nitrogen content increased during the first year of decomposition as the litter remaining mass decreased and the climate was wetter and warmer.

The models generated better predictions when accounting for daily average air temperatures above 0 °C. Our models could be valid for extrapolation to other European climates where annual air temperature and precipitation are correlated, as it was in our case.

6. Acknowledgements

M. Portillo-Estrada, M. Pihlatie and Ü. Niinemets designed the experiments. M. Portillo-Estrada, M. Pihlatie, J. F. J. Korhonen, J. Levula, A. K. F. Frumau, A. Ibrom, L. Horváth and S. K. Jones carried out the field experiment. M. Portillo-Estrada, J.J. Lembrechts and L. Morillas handled and analyzed the data. M. Portillo-Estrada prepared the manuscript with contributions from all co-authors.

667 **Table 1**. Characteristics of the forest and grassland study sites.

Site description	Hyytiälä	Männikjärve	Sorø	Speulderbos	Easter Bush	Bugac
Coordinates	61º50′51″ N 24º17′41″ E	58º52′30″ N, 26º15′33″ E	55º29′13″ N, 11º38′45″ E	52º15′08″ N, 5º15′08″ E	55º51′52″ N, 3º12′25″ W	46º40′59″ N, 19º36′0″ E
Altitude (m)	181	80	40	52	193	111
Climate	Boreal	Hemiboreal	Maritime temperate	Oceanic temperate	Oceanic temperate	Temperate semi-arid (Pannonian)
Ecosystem type	Forest	Forest	Forest	Forest	Intensive grassland	Grassland
Species	*Pinus sylvestris*	*Pinus sylvestris*	*Fagus sylvatica*	*Pseudotsuga menziesii*	*Lolium perenne*	*Festuca pseudovina*
Year of plantation	1962	1975	~1920	1962	1960	
Average stand height in m (year of measurement)	16.3 (2006)	11 (2009)	25 (2006)	32 (2006)	-	-
Total specific leaf area (m^2 kg^{-1})	8.13	6.05	28.65	9.39	17.78	24.47
Initial litter C content (%)	46.68	46.69	45.87	48.31	44.18	44.01
Initial litter N content (%)	0.39	1.24	0.98	1.52	0.67	1.62
Start date (year 2009)	October 5th	October 9th	November 17th	November 19th	November 2nd	November 9th
Decomposition period (d)	368	357	359	367	367	376
Total cumulative air temperature (°C day) *	2404	2759	2969	3574	3153	4193
Annual mean air temperature (ºC)	3.4	5.1	7.6	9.4	8.3	10.9
Annual mean soil temperature (ºC)	5.6	7.7	7.4	8.3	8.2	11.4
Precipitation (mm)	511	725	878	871	744	838
FAO soil type	Haplic podzol	Histic gleysol	Oxyaquic hapludalf	Orthic podsol	Eutric cambisol	Chernozem
Soil water content (%)	23.95	28.73	21.13	38.57	27.57	9.96
Soil texture	Sandy loam	Sandy loam	Loamy sand	Silty sand	Sandy loam	Loess
Soil depth (cm)	61	200	85	100	100	50
Soil pH (5 cm)	3.3	2.2	4.6	3.7	5.1	7.3

668 * Cumulative degree-days accounting for days with mean temperature higher than 0 °C over the
669 decomposition period.

670

671 **Table 2.** Individual estimates (with *t*-value and *P*-values) of the parameters modeled in Equations
672 2 to 9. The predictors which contain "$site_g$" apply for models corresponding to grassland sites. In these
673 cases, the resulting value is the result of the addition of the original predictor lacking of "$site_g$" and the
674 predictor containing "$site_g$". P_c is cumulative precipitation, $T_{c,a>0}$ is the cumulative of daily average air
675 temperatures higher than zero Celsius degrees, W_c is the cumulative daily average soil water content,
676 P is mean annual precipitation, $T_{a>0}$ is mean annual temperature accounting for days with positive
677 temperatures, W is mean annual soil water content, and S_{LA} is the total specific leaf area.

Predictor	Independent variable			
	Remaining litter mass (M_r) (% relative to initial)	Remaining litter C content (C_r) (% relative to initial)	Remaining litter N content (N_r) (% relative to initial)	k decomposition rate ($year^{-1}$)
Intercept	94.50946 (37.5; < 0.0001)	117.86852 (96.5; < 0.0001)	187.51119 (15.9; < 0.0001)	4.7107576 (3.30; 0.007)
Intercept + $site_g$	-9.87787 (-2.25; 0.087)	-18.63872 (-16.3; 0.0001)		0.7145248 (5.18; < 0.0003)
P_c	-0.04873 (-8.07; < 0.0001)			
$T_{c,a>0}$	0.00959 (7.78; < 0.0001)	-0.00041 (-2.72; 0.0068)	0.03156 (7.66; < 0.0001)	
$T_{c,a>0}$ + $site_g$	-0.01018 (-13.3; < 0.0001)			
W_c	-0.00206 (-7.97; < 0.0001)			
M_r		-0.17172 (-12.6; < 0.0001)	-0.92815 -7.16; < 0.0001)	
M_r + $site_g$		0.18253 (12.5; < 0.0001)		
M_r:$T_{c,a>0}$			-0.00037 (-6.07; < 0.0001)	
P				-0.0040002 (-2.55; 0.027)
$T_{a>0}$				-0.8600745 (-3.89; 0.0025)
W				0.0216207 (8.94; < 0.0001
S_{LA}				0.0213956 (1.71; 0.11)
S_{LA} + $site_g$				0.0362101 (5.67; 0.0001)
P:$T_{a>0}$				0.0008268 (3.42; 0.0057)
$T_{a>0}$:S_{LA}				-0.0037277 (-2.44; 0.033)

678

679 **Figure 1**. Average remaining leaf litter mass during a reciprocal litter transplantation experiment
680 of four tree litter types during decomposition in four forest sites (a, b, c and d) and grass litter types
681 during decomposition in two grassland sites (e, f). Different symbols stand for different sites of litter
682 origin (and typically a different species, except the northernmost sites Hyytiälä and Männikjärve):
683 Pinus sylvestris (○) from Hyytiälä (Finland), P. sylvestris (▽) from Männikjärve (Estonia), Fagus
684 sylvatica (△) from Sorø (Denmark), Pseudotsuga menziesii (□) from Speulderbos (Netherlands) (e)
685 Festuca pseudovina (◇) from Bugac (Hungary) and (f) Lolium perenne (●) from Easter Bush (UK).
686 Data points are the average of three replicate litter decomposition bags (maximum standard error
687 between replicates during the decomposition of 4.7%, not plotted). The shadowed areas correspond to
688 the winter period where the litter bags were covered by a snow layer of at least 3 cm. Panel (g)
689 corresponds to early-stage decomposition for tree litter types in Hyytiälä. Table 1 provides details of
690 the sample sites and litter characteristics.

691 **Figure 2.** Average remaining biomass during first year decomposition of leaf litter of four tree
692 species in four forest sites (a and b) and grass litter from two species in two grasslands (c and d)
693 across Europe (see Table 1 for details). The cumulative air temperature is the sum of daily average
694 temperatures above 0 °C from the beginning of the decomposition period until the date of litter
695 collection for every litter bag. The cumulative precipitation is the sum of daily precipitation (in mm)
696 from the beginning the decomposition period until the date of litter collection. The solid lines
697 represent the Pearson's linear regression best fit (n = 336 for forest sites and n = 72 for grassland
698 sites).

699 **Figure 3.** Litter decomposition traits of four different tree litter species with different origin
700 decomposed in four European sites with different mean annual temperature (T_a) and mean annual
701 precipitation (P). Symbols as in Fig. 1. Data corresponding to the same origin of litter are connected
702 with a solid line to visually evaluate the evolution of the trait across the T_a and P range. The dashed
703 line represents the Pearson's linear regression best fit of all the data. Traits are first-year
704 decomposition k rate (a and b), percentage of mass loss after one year of decomposition relative to
705 initial mass (c and d), estimated litter turnover time (e and f), and ratio between final litter N content
706 (N_f) after one year of decomposition and the initial nitrogen content (N_0).

707 **Figure 4.** Total C, N and C:N ratio relative to the initial level at the beginning of the
708 decomposition period. The data correspond to reciprocal litter transplantation experiments with leaf

litter from forests sites: *Pinus sylvestris* (Hyytiälä, Finland), *Pinus sylvestris* (Männikjärve, Estonia), *Fagus sylvatica* (Sorø, Denmark), and *Pseudotsuga menziesii* (Speulderbos, Netherlands); and grassland sites: *Lolium perenne* (Easter Bush, UK) and *Festuca pseudovina* (Bugac, Hungary). Data points (N = 112 for tree litter and N = 24 for grass litter) are the average value of three litter bags. In (a), the dashed line represents the best logarithmic fit to the data. The inset in (c) represents the N content in leaf litter during the first ten days of decomposition. Symbols stand for *P. sylvestris* from Hyytiälä (○) and Männikjärve (▽), *F. sylvatica* (△), and *P. menziesii* (□).

Figure 5. Second-order polynomial relationship between the cumulative litter mass loss (in percentage of initial) of leaf litter of *Pinus sylvestris* (Hyytiälä, Finland), *Pinus sylvestris* (Männikjärve, Estonia), *Fagus sylvatica* (Sorø, Denmark), and *Pseudotsuga menziesii* (Speulderbos, Netherlands), *Lolium perenne* (Easter Bush, UK) and *Festuca pseudovina* (Bugac, Hungary) and the litter N content relative to initial during a reciprocal litter transplantation decomposition experiment. Data points (n = 136) are the average value of three replicate litter bags.

Figure 6. Modeled data using equations 2-8 plotted against observed data: (M_r) the percentage of remaining litter mass relative to the initial value, (k rate) litter decomposition rate constant, and the percentage of carbon (C_r) and nitrogen (N_r) content in litter relative to the initial value. For reference see 1:1 solid lines.
